Background
Adolescent females are at significant risk for sustaining an ACL injury. The Y-Balance Test (YBT) is frequently used to evaluate neuromuscular control and lower extremity function. However, few studies have quantified 2D lower extremity kinematics during performance of the YBT, and there is an absence of kinematic data specific to at-risk adolescent females.

Purpose
To examine lower extremity joint kinematics during execution of the YBT by healthy and ACL-injured adolescent females.

Study Design
Prospective cohort.

Methods
Twenty-five healthy and ten ACL-injured (mean time from injury 143 days) adolescent females were assessed using the YBT. Sagittal and frontal plane knee and ankle motion was video recorded during execution of the YBT anterior reach movement. Ankle dorsi-flexion, knee flexion, and knee valgus angles were quantified via kinematic analysis. ANOVAs with a post hoc Bonferroni correction were used to compare YBT scoring (%LL) and kinematic data between groups. Pearson product-moment correlations determined the relationship between kinematic data and YBT scoring.

Results
Healthy and ACL-injured subjects demonstrated similar YBT scores and lower extremity kinematic data. Healthy subjects demonstrated a weak positive correlation between ankle dorsiflexion and YBT scoring, and a weak negative correlation between knee valgus and YBT scoring. These relationships did not exist for ACL-injured subjects. Kinematic data for both groups also demonstrated a large degree of variability, regardless of YBT score.

Conclusions
Adolescent females frequently utilize a variety of lower extremity movement strategies when performing a functional movement task, and scoring on the YBT offers limited insight regarding lower extremity joint kinematics and ACL-injury risk in a physically active adolescent female population.
Lower Extremity Kinematics of the Y-Balance Test in Healthy and ACL Injured Adolescent Females

Level of Evidence
Level 3.

INTRODUCTION

The anterior cruciate ligament (ACL) is one of the most common sites of orthopedic injury, with an annual incidence of 68.6 per 100,000 person-years in the general population. While risk of ACL injury is significant for both sexes, adolescent females have a 1.6-fold greater rate of ACL injury per athletic exposure than adolescent males, with the peak incidence (227.6 per 100,000) of ACL injury occurring in girls 14-16 years of age. Research seeking to explain this gender disparity has frequently focused on modifiable biomechanical and neuromuscular factors that may influence lower extremity kinematics and the performance of functional movement tasks.

Functional movement testing that involves single-leg squats, lateral step-downs or various jump landing tasks suggests that dynamic knee valgus measures may be predictive of ACL injury. Initial investigations comparing sexes suggest that females demonstrate greater alterations in lower extremity kinematics, and deficits in dynamic balance and postural stability when performing the same movement tasks. Beyond this, the dynamic knee valgus angle has also been demonstrated to influence ankle joint kinematics. As such, further clinical research is needed to clarify the relationship between the knee valgus angle and lower extremity kinematics in an at-risk adolescent female population.

The Y-Balance Test (YBT) is a dynamic balance test that is frequently used in clinical and research settings to assess lower extremity function. Performance on this test is quantified as a measure of maximal reach distance in a specific direction, or as a calculated composite score (average distance of all reach directions). Dynamic balance testing is frequently used as a screening tool to identify individuals at risk of lower extremity injury; to assess deficiencies following injury; or to monitor rehabilitation progress. Lower test scores have previously been associated with an increased risk of ACL injury, and following ACL reconstruction. Neuromuscular education and balance training programs have been reported to improve scoring on dynamic balance tests such as the YBT. However, few investigators have examined whether a link exists between kinematic joint measures for the lower extremity and performance on dynamic balance tests such as the YBT, and currently there is an absence of data which is specific to an at-risk adolescent female population.

The purpose of this investigation was to examine 2D lower extremity joint kinematics during execution of the YBT by healthy and ACL-injured adolescent females. The study had three specific aims: 1) Measure and compare the YBT reach distances for healthy and ACL injured adolescent females; 2) Measure and compare the ankle and knee joint angles of healthy and ACL injured adolescent females when performing the YBT anterior reach movement; and 3) Determine whether a relationship exists between lower extremity kinematic measures and scoring on the YBT anterior reach movement in healthy and ACL injured adolescent females.

METHODS

PARTICIPANTS

Following institutional ethics approval (H2014:302), healthy and ACL-injured adolescent females were recruited from the community to participate in this clinical study. Twenty-five healthy adolescent females and an exploratory group of 10 ACL-injured adolescent females consented to participate. Healthy subjects reported no recent trauma to the lower extremity; subjects in the ACL-injured group had their injury confirmed via orthopaedic consult and magnetic resonance imaging. All participants completed a standardized screening protocol which indicated that they had no knee joint effusion, were able to fully flex and extend the knee joint through a full range of motion, had no quadriceps lag with an active straight-leg raise, had quadriceps strength of at least 75% of the unaffected leg and were able to perform 10 consecutive single-legged hops pain free. All participants were female, 12-18 years of age, with no history of lower extremity injury (other than ACL trauma in the injured group) or concussion in the prior six months. The height, weight, and BMI of all subjects were recorded. Knee joint laxity for all subjects was evaluated using the KT-1000 (MEDmetric Corp., San Diego, CA). Maturation status was determined using the self-reported pubertal maturation observational scale (PMOS); leg dominance was determined by preference for kicking a ball; and information regarding sport participation for each participant was documented.

YBT TESTING FOR DYNAMIC BALANCE

All subjects completed the YBT (Move2Perform, Evansville, IL) according to previously described and standardized procedures. Following completion of the practice trials, the distance from the YBT apex of the most proximal edge of the reach indicator was recorded for the first test trial while participants performed movements in three directions: anterior (ANT), posteromedial (PM) and posterolateral (PL). The dominant (or ACL deficient) limb served as the support leg. All reach distances were normalized as a percentage of each participant’s stance-limb length (%LL), and measured from the anterior superior iliac spine to the most distal aspect of the ipsilateral medial malleolus in a supine lying position.

KINEmATIC ANALYSIS OF LOWER EXTREMITY JOINT ANGLES

For the purpose of this investigation, only the YBT anterior (ANT) reach direction was recorded and used for kinematic analysis. Previous research suggests that this reach direction served as a significant discriminator in predicting risk of lower extremity injury, and pilot testing revealed that kinematic data from the ANT reach direction demon-
strated the greatest accuracy. Two HD video cameras (Sony Handycam HDR-UX20, Sony Corp., Minato, Toyko, Japan) were used to collect lower extremity kinematic data while each participant performed the YBT in the ANT direction. One camera was positioned three meters in front of each subject to capture a full frontal-plane view, while the other camera was positioned three meters lateral to each subject to capture a sagittal view. All digital images were coded and saved for subsequent video analysis. Analysis was only completed for the dominant limb of the healthy subjects and the injured limb of the ACL-injured participants.

Open-license video analysis software (Kinovea 0.8.15) was then used to quantify three joint angles at the point of maximal ANT reach distance when performing the YBT: (1) the degree of knee joint flexion in the sagittal plane; (2) the degree of ankle joint dorsiflexion in the sagittal plane; (3) the knee valgus angle in the frontal plane. The same anatomical landmarks were used as reference points for calculating the joint angles of all participants. Selection of these landmarks was based on methodologies previously described in the literature. Each kinematic measure was calculated using the Kinovea software (Figure 1A & B). The angle of knee flexion in the sagittal plane was determined by measuring the angle created between the lower leg and the posterior thigh with the neutral or starting angle being considered full extension (180°). The angle of ankle dorsiflexion in the sagittal plane was determined by measuring the angle created between the long axis of the foot and the lower leg with neutral being considered 90° of dorsi-flexion while in a standing position. The angle of knee valgus in the frontal plane was determined by measuring the angle created between the lateral thigh and the lower leg with neutral being considered full extension (180°). This orientation allowed the knee valgus angle to be reported as a positive value.

STATISTICAL ANALYSIS

A power analysis (n=2[(1.96+0.84)6.7/8]²) from a previous study of healthy recreationally active adolescent females performing the ANT reach of the YBT indicated that a minimum of 12 healthy subjects would be required to adequately power this investigation. ANOVA testing was used to analyze for differences between the healthy and ACL-injured subjects on demographic, anthropometric, YBT reach distances and the lower extremity joint angles. An alpha level of p < 0.05 was set to determine statistical significance. The relationship between kinematic angles and the YBT scoring was evaluated using Pearson product-moment correlations. Correlation coefficients (r) of 0.25-0.49, 0.50-0.74, and 0.75-1.0 were considered to represent weak, moderate and strong relationships. The 95% confidence interval (CI) for the YBT reach distances of the healthy subjects was used to group subjects for comparison. ANOVA testing between groups with a post hoc Bonferroni correction of p < 0.0167 were used to determine statistical significance. In addition, we performed single-subject analysis for each variable using the healthy subject 95% CI’s for comparison.

RESULTS

Results indicated that the ACL-injured group was significantly older than then the healthy group (Healthy: 14.0±1.3 yrs; ACL injured: 16.3±1.6 yrs, p < 0.001). With the ex-

Table 3 illustrates the relationship between the YBT ANT reach distance and lower extremity joint angles. Pearson correlation coefficient testing for the healthy subjects suggested that there were weak relationships (0.25-0.49) between the YBT ANT reach distance and the degree of ankle dorsiflexion (positive), the degree of knee valgus (negative), and that there was a trend towards a positive relationship with the degree of knee flexion. These relationships were only significant for the ankle dorsiflexion and knee valgus angles. Analysis of data for the ACL-injured group suggested that there were no relationships between lower extremity joint angles and YBT ANT reach scores.

Using YBT ANT reach data, 95% confidence intervals (CI) were calculated for each group. Subjects were then stratified into three groups: (1) Above 95% CI = 72.5 ± 2.8 %; (2) Within 95% CI = 64.7 ± 1.5 %; and (3) Below 95% CI = 58.2 ± 3.3 %. A comparison of the kinematic data across the three groups indicated that there were no significant differences for either the healthy participants or the ACL injured participants (Table 4).

These same three YBT ANT reach distance groupings (above, within or below 95% CI) where then used to perform single-subject analyses. Data illustrated that there was little consistency in the movement patterns demonstrated about the ankle and knee joints by either the healthy or ACL-injured subjects when performing the ANT reach of the

DISCUSSION

This is one of the first investigations to examine lower extremity kinematics during performance of the YBT in both at-risk healthy and ACL-injured adolescent females. Results suggested that there were no significant differences between the healthy and ACL-injured subjects on YBT scoring, or the lower extremity joint angles observed when partic-
participants performed the YBT ANT reach direction. Data for the healthy adolescents indicated that there were only weak correlations between scoring on the YBT and the angle of ankle dorsiflexion (larger YBT scores were associated with a greater degree of ankle dorsiflexion) and the angle of knee valgus (larger YBT scores were associated with less knee valgus), but there was little relationship between the angle of knee flexion and YBT ANT reach scoring. Results for the ACL-injured group suggested there were no relationships between any of the lower extremity kinematic measures and ANT reach scoring on the YBT. Interestingly, a comparison of subjects when grouped by their performance on the YBT ANT reach (above, within or below the 95% CI) also failed to identify any consistencies between YBT scoring and lower extremity joint angles (for example: a girl who scored well on the YBT was just as likely to have a large knee flexion angle as a girl who performed poorly). A similar result was observed when single-subject analysis was performed. These findings serve to reinforce the notion that adolescent females frequently utilize a variety of lower extremity movement strategies when performing functional movement tasks typically observed in sport, and suggest that ANT reach scoring on the YBT may offer limited insight regarding lower extremity joint kinematics, and ACL-injury risk in a physically active adolescent female population.

This investigation is among the first to report both dynamic balance and kinematic data that is specific to both a healthy and ACL injured adolescent female population who participate in a variety of recreational sporting activities and is nearing or has recently reached physical maturational age. While data indicated that the healthy group was much younger than the ACL injured group, the only significant difference observed in the anthropometry of the two groups was on the parameter of knee joint laxity (ACL deficient group > healthy group). As such, the results help to fill a significant void that currently exists within the biomechanical and neuromuscular testing literature, and provides important baseline data that is generalizable to a much larger population of adolescent females that is at significant risk for ACL injury during sports participation.

The results serve to extend the findings of previous investigations on dynamic balance which have focused on athletes from specific sports, older age groups, or competitive sport. The literature indicates that dynamic balance scoring can vary greatly, and can be influenced by a host of factors including testing methodologies, the precision of the value reported, and the study population’s age, sex, and competitive level. YBT scoring for our healthy adolescent female population fell within the range of expected scores based on participants age, gender and competitive level – scores were slightly higher than those previously reported for adults; slightly lower than adolescent athlete scoring reported for both sexes; and most similar to scoring from older female participants. Normal function of the proprioceptive, vestibular, and visual systems are all important for dynamic balance, and each of these systems are still maturing and developing during the adolescent period. As such, it is possible that gender and biological changes associated with aging and physical maturation had a significant effect on YBT scoring in the present study; and caution should be used when comparing these data with previous reports for an adult population.

Kinematic data from the current investigation provides important information about lower extremity joint movements during the execution of the YBT ANT reach by a population of healthy adolescent females at significant risk for lower extremity injury. Sagittal plane data for the angle of ankle dorsiflexion and the angle of knee flexion were comparable to previous reports involving dynamic balance testing. Within a general population, dorsiflexion angles typically range from 32° to 39°, and knee flexion angles have been reported to range from 51° to 68°. To date, only one previous investigation has examined the knee valgus angle (mean=14.15±8.36) during performance of the YBT, and this study involved a physically mature population of co-ed university students (mean age of 22.7±2.2 years). Participant knee valgus angle for our adolescent female participants were significantly lower.

than values reported in this earlier study, and are much closer to values reported in another study which evaluated a single leg squat task in 30 physically active young females.\(^9\)

This investigation also examined YBT ANT reach distance and lower extremity kinematics in an exploratory group of ACL-injured participants. Data indicated that YBT reach distance and joint angles were not significantly different when comparing healthy and ACL-injured adolescent females. These findings may suggest that our ACL-injured subjects were able to use some form of neuromuscular control in order to compensate for their ligamentous instability in their knee. Previous research does suggest that a percentage of ACL injured patients, often referred to as "copers", are capable of coordinating muscle activity to dynamically stabilize the knee and resume preinjury activities without episodes of the knee giving-way.\(^{59}\) Having said this, the current investigation of the YBT is the first to include ACL-injured adolescent individuals. Previous investigations of clinical dynamic balance using subjects with ACL injury have used less reliable dynamic balance testing protocols such as the Star Excursion Balance Test (SEBT).\(^{5,33}\) These studies found differences between the healthy controls and the ACL injured participants for the anterior reach direction.\(^8\) Although the YBT and SEBT testing protocols are similar, research suggests that the anterior reach distance performance and kinematic profiles of test subjects are different, and that each test imposes different neuromuscular demands and postural-control strategies on the participants.\(^{26,38,60}\) Thus caution should be used when comparing results from the different forms of dynamic balance testing, and further neuromuscular research which targets ACL-injured subjects is required in order to clarify inconsistencies, and determine whether a difference really exists between injured and healthy limbs during execution of the YBT.\(^5,33\)

Research on an adult population has previously indicated that the angle of ankle dorsiflexion is the best single kinematic predictor of YBT scoring in the anterior reach direction.\(^{27,61}\) Anterior reach YBT scores have also been reported to have a moderate correlation with the angle of knee flexion. But, no significant relationship has been established between YBT scoring and the angle of knee valgus.\(^{27}\) Results for a healthy adolescent female population were in agreement with the results of these earlier investigations, and suggested that a positive weak correlation existed between YBT scoring and the angle of ankle dorsiflexion (ie. subjects who achieved greater ankle dorsiflexion tended to be able reach further on the YBT). However, in contrast to these earlier reports data from this investigation suggested that there was no correlation between the angle of knee flexion and YBT anterior reach scoring, and that a negative correlation existed between a subject’s knee valgus angle and their YBT score (ie. as the angle of knee valgus increased, a subjects YBT anterior reach distance actually decreased). Previous research specific to an adolescent female population has suggested that kinematic assessment of the knee joint may be more important than the ankle joint as females demonstrate a larger dynamic knee valgus position than males when performing functional tasks such as jump landing and single leg squats.\(^{62–64}\) Dynamic knee valgus measures during the execution of functional tasks (such as the YBT) are reported to be predictive of risk for ACL injury in adolescent females.\(^4,5,7,12\) Results from this investigation are in agreement with other reports which suggest that lower YBT scores\(^{19–22}\) and greater knee valgus angles\(^4,5,7,12\) are frequently observed in populations who are at increased risk of ACL injury.

In contrast to the healthy subjects, data for the ACL-injured participants suggested that there was no relationship between lower extremity joint angles and YBT anterior reach scoring. While the large range in scoring and small sample size may have contributed to this finding, it is also possible that anterior/posterior joint instability and participant movement apprehension associated with ACL deficiency resulted in participants being more hesitant or guarded when performing the YBT anterior reach movement.\(^{65}\) As a result, the ACL injured subjects may have subconsciously utilized movement strategies the involved greater range of motion at the hip joint or within the trunk region to achieve similar reach distances while minimizing movements about their injured knee.\(^23\)

Finally, a comparison of the kinematic data between the healthy and ACL-injured groups suggested that there were no significant differences in ankle and knee joint angles when performing the YBT ANT reach direction. These results were confirmed when data was organized by YBT confidence intervals and by single-subject analysis. The sensorimotor system that regulates balance and postural awareness relies on information from the visual, vestibular and somatosensory subsystems.\(^{56}\) However, pubertal growth is reported to inhibit the sensorimotor functions of the lower extremity and lead to awkward movement patterns.\(^{56}\) The variability of movement strategies we observed may be attributed to the fact that our participants were still progressing through or recently completed the maturation process, and as such their neuromuscular control and intersegmental limb coordination were still developing.\(^{56}\) During execution of the YBT, the only instructions given to subjects were to push the reach indicator as far as possible along the pipe in the reach direction while maintaining a unilateral stance with their hands on hips. No tips on how to enhance performance were given.\(^{16,46}\) Kinematic data for individual subjects would seem to suggest that adolescent females use a variety of movement strategies to achieve maximal reach distance, including ankle dorsiflexion, knee flexion and knee valgus. Standardized placement of the hands on hips was used to minimize the influence of upper body/extremity sway, although variations in hip and trunk movement were unavoidable. Balance-correcting strategies of the trunk and hip are often used to maintain one’s center of mass over a base of support and prevent loss of balance during a lower limb reach.\(^{25,27}\) Other investigations indicate that a similar anterior reach distance can be achieved by either flexing the hip and knee of the stance limb, or creating a Trendelenburg position, adducting the hip of the stance limb to lengthen the reach limb.\(^{25}\) Lack of stability at the trunk and hip is suggested to contribute to lateral trunk and Trendelenburg positions, and subsequently a knee valgus position.\(^{4,5,7}\) Unfortunately in this study, hip and trunk kinematic data were unable to be collected because the video cameras were positioned to collect information exclusive to the lower extremity. The specific influence of trunk and pelvic positions on the kinematics of
the lower extremity may reveal more information about the role of distinct or varied positional stabilization strategies during execution of the YBT, and should be examined in future investigations.

This study is not without limitation. The use of 2D video analysis restricted kinematic analysis to only the anterior reach direction of the YBT. Kinematic analysis of posterolateral & posteromedial reach directions are much more complex (due to the additional rotational movements of the trunk and lower extremity), and thus required more sophisticated 3D motion-capture equipment that was beyond the scope of this investigation. Additionally, due to time and lab space constraints in our data collection protocol (eg. multiple participants were being simultaneously evaluated) videotaping was restricted to only the first test trial for each subject. As such, it is possible that subjects may have altered their kinematic approach to performing the YBT over the three consecutive trials of the testing methodology. Kinematic analysis of each of these individual trials may have helped to provide a more reliable depiction of the relationship between lower extremity joint position and scoring on the YBT.

CONCLUSION

The results of this investigation indicate that there were no significant differences in YBT scoring and lower extremity kinematic data in the anterior reach direction when comparing the movement patterns of healthy and ACL-injured adolescent females. Additionally, both groups utilized a variety of lower extremity movement strategies when performing the functional movement task. Reach scoring on the YBT may offer limited insight regarding lower extremity joint kinematics, and ACL-injury risk in a physically active adolescent female population. Although beyond the scope of this study, results from future prospective, longitudinal investigations of both healthy and ACL-injured adolescent females could be used to identify the physical and neurological parameters that influence knee joint motion in this at-risk sporting population.
