International Journal of Sports Physical Therapy
Vol. 17, Issue 1, 2022

The cardiopulmonary system plays a pivotal role in athletic and rehabilitative activities following anterior cruciate ligament reconstruction, along with serving as an important support for the functioning of other physiologic systems including the integumentary, musculoskeletal, and nervous systems. Many competitive sports impose high demands upon the cardiorespiratory system, which requires careful attention and planning from rehabilitation specialists to ensure athletes are adequately prepared to return to sport. Cardiopulmonary function following anterior cruciate ligament reconstruction (ACLR) can be assessed using a variety of methods, depending on stage of healing, training of the clinician, and equipment availability. Reductions in cardiovascular function may influence the selection and dosage of interventions that are not only aimed to address cardiopulmonary impairments, but also deficits experienced in other systems that ultimately work together to achieve goal-directed movement. The purpose of this clinical commentary is to present cardiopulmonary system considerations within a multi-physiologic systems approach to human movement after ACLR, including a clinically relevant review of the cardiopulmonary system, assessment strategies, and modes of cardiopulmonary training to promote effective, efficient movement.

Level of Evidence

5

INTRODUCTION

Systems with multiple levels cannot be fully understood by examining their component parts, as the outcome of their interactions is different from the sum of the parts. Since 2013, the American Physical Therapy Association (APTA) has promoted the movement system in physical therapist practice, education, and research as 'the foundation for optimizing movement to improve the health of society.' Through the integration of body systems and functions, the movement system essentially refers to the body’s ability to produce and sustain movement. Barriers to implementation and validation have arisen since the adoption of the term movement system with efforts ongoing to promote its use. A framework that has been more readily accepted for describing motor control, movement dysfunction, and skill acquisition is a dynamical systems theory approach. Dynamical systems theory aims to explain variability in goal-directed human movement and enhance the understanding of a complex system through its component parts. Similarly, the APTA movement system and dynamical systems theory place importance upon the functions and interactions of component systems in support of the entire system as a whole. A physiologic system, individually, can be representative of a component system that is needed for achieving purposeful, goal-oriented human movement. With this understanding, a multi-physiologic systems approach may offer a useful perspective for clinicians during rehabilita-
tion after anterior cruciate ligament reconstruction (ACLR). The purpose of this clinical commentary is to present cardiopulmonary system considerations within a multi-physiologic systems approach to human movement after ACLR, including a clinically relevant review of the cardiopulmonary system, assessment strategies, and modes of cardiopulmonary training to promote effective, efficient movement.

CARDIOPULMONARY SYSTEM CONSIDERATIONS AFTER ANTERIOR CRUCIATE LIGAMENT RECONSTRUCTION (ACLR)

The cardiopulmonary system has important roles when interacting with other systems such as thermoregulation when performing cardiovascular training,6 providing blood flow to working muscles during strength training,7 and supporting a highly metabolically active nervous system. This is not to mention the association between aerobic activity and improved cognition in older populations8 and enhanced executive function in younger individuals (ages 20–67).9 The cardiopulmonary system, along with other body systems, experiences change after ACLR. Anterior cruciate ligament (ACL) injuries typically occur while landing from a jump or with change of direction, which is common in several team sports such as basketball, soccer, and football.10 These sports require high-intensity intermittent actions interspersed with sustained low-intensity activities. Since most of these sports are predominantly running based these efforts fall under "repeated-sprint ability" (RSA) which is defined as brief sprints (<10s) followed by incomplete (<60s) recovery.11,12 These activity requirements place unique demands on both the anaerobic and aerobic energy systems.13,14 Ultimately all three energy systems (phosphocreatine, glycolytic, aerobic) will be involved during intermittent cycles of sprint-recovery, but the degree to which each energy system is utilized depends on factors including but not limited to the particular sport, the position(s) played, and game/match situation or phase.

For example, a recent systematic review examining the activity demands during basketball reported guards performing more high-intensity movements throughout the course of a basketball game compared to forwards and centers.15 Although the demands for each sport and individual may be unique, the general energy system demands seen across field and court sports (which also tend to be where most ACL injuries occur) are broadly similar.16 After an ACL injury, these energy systems become detrained secondary to the reduction in stimulus in accordance with the specific adaptation to imposed demands (SAID) principle. This shift in ability can be viewed as the envelope moving "to the left" if viewed within the "envelope of function" model.17 This model, initially proposed by Scott Dye for the musculoskeletal system, contrasts the individual's physiological capacity with the task demands on an intensity/duration spectrum and has been adapted for this commentary to apply to the cardiopulmonary system, as depicted in Figure 1. The goal of rehabilitation is to shift the envelope of function to the right so that the task demands fall below the maximum tolerated line. Unfortunately, rehabilitation oftentimes fail to fully address this shift, resulting in athletes returning to play without the energy system development needed for their sport.18

Since clinical tests of the cardiopulmonary system predominantly measure change in performance as a proxy for cardiopulmonary system changes, it is important to understand that performance can improve due to a combination of underlying factors and may not reflect the adaptations desired. For example, cardiac output is the product of heart rate (HR) and stroke volume (SV) which is further determined by venricular volume and ejection fraction. An increase in performance after an intervention to address central factors such as SV could be seen due to an increase in HR alone which would indicate a failed intervention but still show an increase in performance. As such, the clinician must interpret test results with caution and rely on sound exercise prescription principles that maximize the probability of seeing the desired adaptations being addressed. The impacts of undergoing ACLR on the cardiopulmonary system are under-represented in the scientific literature compared to other areas of the rehabilitation and recovery process. Most of the available literature addressing detraining of the cardiopulmonary system focuses on issues secondary to cessation of activity in an uninjured population. In turn, much of the available literature on detraining and re-training post-ACLR focuses on neuromusculoskeletal impairments and return to sport.19

CARDIOPULMONARY SYSTEM REVIEW

Competitive athletics impose high demand upon the cardiorespiratory system. For example, during a 90-minute soccer game, players have been reported to run ~10km at intensities as high as 75% of their peak oxygen uptake (VO2 peak) as well as covering 215 +/- 100 meters at sprint speeds.13,20,21 Significant demands on the cardiopulmonary system22 are seen across a wide variety of sports including those viewed as anaerobic such as American football23 which requires wide receivers to cover 5,530.6 +/- 685.6 yards in a game that includes 22 +/− 8 max acceleration efforts.13,21 Human physiology relies on the energy stored in one of the phosphate bonds in adenosine triphosphate (ATP) to power all activities. Breaking this bond

Figure 1. Physiological Response to Task Demands

changes ATP to adenosine diphosphate (ADP) which must then be converted back to ATP by one of the three main energy systems: phosphocreatine (ATP-Pcr), glycolytic, and aerobic. The cardiopulmonary system plays a key role in supplying the required energy resources and shuttling off by-products such as carbon dioxide, lactate and H+ ions. The following section briefly outlines some of the key considerations for the various energy systems.

PHOSPHOCREATINE (ATP-PCR) SYSTEM

An important component of the ATP-Pcr system, creatine-phosphate (CP), assists with anaerobic production of ATP for quick bursts of activity and muscle contractions in response to the demands of the sport as outlined in Table 1.22–26 These CP levels fall significantly during brief intense activity, such as during high-speed efforts in soccer where they can drop below 75% of resting levels due to the energetic demands.27,28 In fact, it has been estimated that the actual drop in CP may be closer to 60% of the resting levels.27,28 It has been reported that CP levels in individual muscle fibers experience near depletion when fatigue occurs as a result of repeated intense activities showcasing the importance of the energy system’s ability to rapidly replenish.27,29 This system is limited by the storage of ATP and phosphocreatine, relies on the aerobic system for recovery, and is limited in trainability.18,30 Due to its nature and the limited adaptive potential of this system it tends to both train and detrain rather quickly (<2-3 weeks) which means that it is best trained and maintained via brief and frequent exposures when needed to supplement practice and game demands.18

GLYCOLYTIC SYSTEM

Lactate is a key byproduct of the glycolytic system due to cellular metabolism in muscles working to meet the demands of exercise.31,32 This process occurs when pyruvate production exceeds the uptake ability of the glycolytic muscle fiber resulting in its reduction to lactate.31,32 This molecule has had an interesting history and was viewed as a waste product and cause of fatigue for most of the 20th century. The reality is that it acts a buffer against fatigue due to its use of 70-75% of the released H+ ions for transport out of the working muscle and becomes an important energy source during high intensity exercise when it is aerobically metabolized by an oxidative muscle fiber.31 It can also be used by the heart, liver, or brain as an energy source and functions as a pseudo-hormone where it interacts as a signaling molecule with multiple anabolic pathways and plays a role in norepinephrine release and brain plasticity.31 Multiple studies have described the average blood lactate threshold ([BLA]) among athletes during soccer games to be 2-10 mmol with muscle lactate concentrations ([MLa]) increasing to approximately 4 mmol/kg after periods of intense activity, which is an increase of 400% from resting values.28,33–37 Lactate can be converted to pyruvate and subsequently glucose through the process of gluconeogenesis where it functions as a fuel source for the aerobic system.

Glycogen is a "readily mobilized storage form of glucose" which is an important energy source during prolonged athletic activity.38 Studies have reported inconsistent levels to which glycogen is reduced during the course of a soccer game, with some noting decreases of 90% (from 100 mmol/kg to 10 mmol/kg) while others report decreases of only 35-60% (from 100 mmol/kg to 40-65 mmol/kg).27 Much like with CP levels, muscle glycogen levels have been found to decrease dramatically in individual muscle fibers in direct relation to the duration of activity over the anaerobic threshold regardless of muscle fiber type.27,28 The glycolytic energy system is fairly trainable but produces energy at a slower rate (50% of AT-Pcr) and also adapts at a faster rate compared to the aerobic system (~3-4 weeks).18

AEROBIC SYSTEM

The aerobic system produces ATP at the lowest rate per unit time but is limited by oxygen supply and uptake as well as the availability of various substrates and enzymes. It also plays a significant role in recovery between intense bouts and contributes a significant portion of the ATP used during repeated sprints. This system is highly trainable due to its high ceiling for adaptation but also takes much longer to train (four to eight weeks for initial changes and three to four months for significant adaptations) compared to the previous two systems. After cessation of training, the athlete’s aerobic performance can be maintained for ~1 month with increases in HR at similar intensities compensating for early detraining effects such as blood volume changes and loss of ventricular size. As detraining continues, all adaptations will reverse at a rate similar to the initial adaptation and by 3-4 months the majority of previous adaptations will have been lost.

Of primary concern following ACLR is the effect of detraining "partial or complete loss of training-induced anatomical, physiological and performance adaptations" on cardiovascular fitness. Reductions in cardiovascular function may influence the selection and dosage of interventions that are not only aimed to address cardiopulmonary impairments, but deficits experienced in other systems as well. In an athlete who has undergone ACLR, long term (>4 weeks) changes in cardiovascular fitness are generally the most relevant. Studies on detraining show a longer term drop of maximum rate of oxygen consumption (VO2max) in highly trained individuals of up to 20% after cessation of exercise. In trained individuals, this decrease in VO2max was much more significant with some studies showing a complete regression to untrained levels in a similar timeframe after cessation of exercise. When examined in a ACLR population, VO2max was 20% lower pre- and 15% lower six months post-ACLR in professional soccer athletes when compared to controls. However, while VO2max is a metric that is often used it suffers from lack of ability to predict performance, especially in RSA type settings, and changes in VO2max do not always accurately reflect underlying adaptations to training and detraining. In the same study on soccer players, athletes post ACLR had significantly lower running speeds compared to controls pre- and six months post-ACLR at both anaerobic threshold (VT1), which is the point at which lactate begins to accumulate within the blood and ventilation rate increases in an attempt to clear the increased production of carbon dioxide (CO2), and lactate threshold (VT2) which occurs when the buffer system is no longer able to clear lactate at the rate it is produced.

The acute deconditioning following an ACL injury results in a reduction in peak VO2 (VO2peak) due to changes occurring both in the peripheral muscle and due to myocardial remodeling. Even after completing a full ACLR rehabilitation program many athletes may still demonstrate reduced VO2peak and ventilatory threshold (VT). This reduction in aerobic conditioning is of concern, as certain field tests have been shown to be valid assessments of estimating aerobic endurance performance while also holding predictive value for lower extremity musculoskeletal injuries. Attaining adequate sport-specific fitness levels may be important to better prepare for the demands of the sporting tasks. Participating in a preseason seven-week conditioning program that included cardiovascular conditioning was associated with reduced lower extremity injury rates compared to those who were untrained, and should be included as part of a comprehensive conditioning program. By adequately training cardiopulmonary fitness, this may have an impact on musculoskeletal health and should be considered when taking a multi-physiologic systems approach to rehabilitation after ACLR.

RESULTS OF DETERTRAINING

CARDIOVASCULAR

Complete cessation of exercise training (detraining) results in a multitude of physiological changes in the cardiovascular system which are initiated primarily by reductions in circulating plasma volume. Significant reductions in plasma volumes have generally been reported following four weeks of detraining but may occur after only two days. This reduction in circulating plasma volume reduces cardiac preload which induces a concomitant remodeling to the heart. This cardiac remodeling appears to follow a structure-specific pattern. Pedlar et al reported that four weeks of detraining caused significant reductions in left ventricular (LV) wall thickness, LV mass, and right atrial area. However, after eight weeks of detraining a significant reduction in right ventricle chamber size was observed but without any additional changes to the LV wall thickness. Along with these structural changes to the heart, many functional changes occur. Following two to four weeks of detraining, a 12% reduction in exercise SV, and an 11% increase in submaximal HR have been reported. These changes to HR responses following detraining have been attributed to multiple mechanisms including reduced parasympathetic outflow to the sinoatrial node, altered baroreceptor sensitivity, and beta-adrenergic hypersensitivity. Additionally, total heart volume (THV) and ventricular end diastolic volume decreases following ACLR, however, it appears as though only THV spontaneously improves upon reinitiating exercise training. Reductions in end diastolic volume, SV, cardiac output (CO), ejection fraction, hemoglobin concentration, and hematocrit and increase resting heart rate have been observed in soccer players after ACLR. Altogether these physiological adaptations to the heart following detraining improve CO and reduce peak exercise capacity, which in turn may impact other interventions that target other body systems that ultimately work together to create efficient, goal-directed movement.

In addition to changes in the heart, detraining may augment circulatory and ventilatory responses to exercise. After two to four weeks of detraining has been shown increase total peripheral resistance, reduce skeletal muscle capillarization, and reduce conduit artery diameter and blood flow. These vascular changes impair perfusion and oxygen delivery to working muscles and also increase cardiac afterload. The changes in blood flow to working muscles may be an important physiologic system integration especially...
after ACLR, as recovery of quadriceps strength is a key facet of rehabilitation and impacts patient outcomes.\textsuperscript{57,58}

**PULMONARY/VENTILATORY**

The effects of detraining on ventilatory responses are inconsistent in the literature. Attenuated initial ventilatory responses have been reported following 20 days of inactivity.\textsuperscript{59} Detraining has also been shown to reduce maximal ventilatory volume and oxygen pulse during exercise.\textsuperscript{40} However, these effects on the respiratory system appear to be more pronounced in highly trained athletes.\textsuperscript{40} No significant changes in ventilatory responses or markers of ventilatory efficiency (VE/VO\textsubscript{2}CO\textsubscript{2} slope) were found following six weeks of detraining in young soccer players.\textsuperscript{60}

**CARDIOPULMONARY SYSTEM ASSESSMENT AFTER ACL RECONSTRUCTION**

Cardiopulmonary function following ACLR can be assessed using a variety of methods, depending on stage of healing, training of the clinician, and equipment availability. It is important to consider what being measured when a test is chosen. Broadly speaking, the workload and the individual’s response can be divided into external (the workload imposed on the organism), internal (the physiological response to the external workload), and psychophysiological (the perception of effort by the individual).\textsuperscript{61} Heart rate is one of the most common methods used to evaluate and predict overall cardiorespiratory fitness for team-based athletics; however, other assessments have been utilized including blood lactate concentration ([BLa]), estimated VO\textsubscript{2}max, rating of perceived exertion (RPE), metabolic equivalent testing (MET), respiratory exchange ratio (RER), and VT.\textsuperscript{13,14,62} A method for determining overall fitness that has become more accessible due to advances in technology is energy expenditure (EE).\textsuperscript{63,64} EE is a useful metric as it can be expressed as the amount of energy an individual expends across several conditions, which may include rest, submaximal/maximal exercise, or recovery after exercise.\textsuperscript{65} EE can be assessed in a variety of ways including wearable options like accelerometry, pedometry, and more intensive options such as indirect calorimetry (IC) or the doubly-labeled water (DLW) method.\textsuperscript{64}

**HEART RATE**

HR assessment is a measure of internal workload and has many options of implementation such as a manual or automated measure of pulse rate, electrocardiogram (ECG), and Holter machine monitoring. These methods have been utilized since at least the 1970’s to quickly assess HR with varying degrees of accuracy.\textsuperscript{56,67} However, starting in the 1980’s, access to HR monitoring via ECG chest straps and wrist-worn electronic devices have been the preferred option. HR monitoring with chest-worn ECGs as well as wrist-worn optical blood flow monitors have provided accurate HR readings when compared to ECG, though it is believed that chest-worn devices provide greater accuracy.\textsuperscript{56,68–70} As with any measurement, the proper use of the device is key for determining an accurate HR regardless of the model. Speed is another factor that can influence readings with some data showing the accuracy of HR monitoring devices may decrease with increased speed, particularly when running.\textsuperscript{67–70} While there is a large amount of data on HR in team sport athletes at various levels of play, most of this research has been conducted on male subjects.

**RATING OF PERCEIVED EXERTION (RPE)**

The use of RPE is based on the subject’s perception of effort to the external load and is therefore a measure of psychophysiological load. However, it has been shown to correlate well with other measures such as HR and blood lactate levels.\textsuperscript{71} Gunnar Borg developed the Borg Scale in 1982 to quantify perceived exertion during activity and modeled it on measures of heart rate.\textsuperscript{72} In the Borg Scale, the participant typically rates their perceived level of exertion on a scale of 6 to 20, with higher numbers representing a greater effort. A modified version of the Borg Scale (CR-10) has also been developed with perceived exertion rated on a 1 to 10 scale.\textsuperscript{73,74} The Borg Scale is highly correlated with HR as well as [BLa] and has been found to be a valid method for estimating session workloads.\textsuperscript{71} While both the original or modified Borg Scale can be utilized at various stages throughout the course of rehabilitation following ACLR, the modified scale tends to be easier to implement. This is especially true if using session RPE which gives a rating of total session workload (sRPE). The sRPE is calculated by taking the total duration of the session and multiplying it by the RPE obtained after the session ends. In general, it is advised that the sRPE be taken a short period after the session has ended but there is no need to wait the original 30 minutes.\textsuperscript{18} For reliability, it is important to use both the verbal and visual anchors and perform the collection the same way every time.

**CARDIOPULMONARY EXERCISE TESTING (CPET)**

While various field tests can provide an assessment of aerobic fitness which may estimate VO\textsubscript{2}peak, the most accurate method is the use of Cardiopulmonary Exercise Testing (CPET) with analysis of expired ventilatory gases.\textsuperscript{75,76} Guidelines on standardized testing parameters have been provided by various professional organizations.\textsuperscript{76} Most protocols utilize either a stationary cycle ergometer or treadmill.\textsuperscript{76} There have also been protocols adopted using motor driven skate treadmills for hockey players\textsuperscript{77} and treadmill skiing. Additional measures obtained from CPET such as VT are also indicators of training status and physical condition across sports.\textsuperscript{21,78} There is some data to suggest the implementation of CPET such as in pre-season where VO\textsubscript{2}peak was shown to be an independent predictor of injury at any point during the competitive season in collegiate soccer players.\textsuperscript{79}

Despite the well-established relationship between the data obtained from CPET, notably VO\textsubscript{2}peak and VT, its use in return to sport decision making following ACLR is limited, likely due to equipment availability and time constraints. Most of the available literature investigating the role of CPET for return to sport following ACLR has been in soccer players.\textsuperscript{13} De Almeida et al reported that even after...
six months of rehabilitation following ACLR in professional soccer players both VO2peak and VT were still reduced compared to non-injured athletes.\textsuperscript{15} It is worth noting that VO2peak typically remains stable within season and between seasons in elite soccer players.\textsuperscript{80} Therefore, the differences in the study by De Almeida essentially reflects reductions compared to population-based norms. These results suggest that CPET can be used to accurately identify persistent impairments in VO2peak and other markers of aerobic fitness following ACLR. These measurements obtained by CPET can be compared to sport specific measures to accurately and objectively determine if an athlete has attained the requisite aerobic fitness for their sport. The use of preseason CPET may also permit athlete-specific comparisons following ACLR and assist in screening and injury risk reduction processes.

**MAXIMUM AEROBIC SPEED (MAS)**

Much like RPE, maximum aerobic speed (MAS) is one of the most clinically friendly ways to both assess an individual’s fitness and obtain a metric that can be used for programming. This combined with the fact that it only takes five minutes makes it a very easily implemented option. This test is designed to give the maximum speed at which the task can be performed while relying on the aerobic system.\textsuperscript{18,81,82} The test can be performed on any piece of equipment that allows for a measurement of total work done but traditionally is used with running, biking, or rowing. To perform the test, the individual is encouraged to go as far/hard as they can for a 5-minute period after which the total distance is divided by time. For a detailed review of prescription in rehabilitation based on MAS see Morrison et al.\textsuperscript{18}

**WINGATE TEST**

The Wingate Test is one of the most frequently utilized tools for assessing anaerobic conditioning and muscle power production. The test involves cycling with 100% effort on a stationary bike ergometer for 30 seconds with a resistance, sometimes referred to as breaking force, of 7.5-8.9% of the participant’s body mass, though some authors advocate for the resistance to be as high as 11%\textsuperscript{83,84} The Wingate Test has been researched significantly and has been determined to be a reliable assessment.\textsuperscript{84,85} Normative values have been established for male athletes, however, it’s validity among female athletes has been questioned.\textsuperscript{86,87} Reference values have been established for males and females across multiple sports and various levels of play.\textsuperscript{88}

The Yo-Yo intermittent recovery test requires running at fast speed as well as multiple changes of direction. Therefore, the rehabilitation specialist should be confident that the athlete has reached the appropriate rehabilitation milestones prior to administering the assessment. It is the perspective of the authors that the Yo-Yo intermittent recovery test is usually conducted beginning six months following ACLR depending on clinical status.

**MODES OF CARDIOPULMONARY SYSTEM TRAINING**

The mode and progression of cardiopulmonary training is typically determined by several factors such as postoperative timeframe, clinical status, and training goal(s). The reader is referred to Buckthorpe et al 2020\textsuperscript{90} for a ten task-based progression following ACLR. The tasks in the progression include walking, bilateral foundational movements, unilateral foundational movements, bilateral landing, running, bilateral plyometrics, unilateral jumping/landing, unilateral plyometrics, pre-planned multidirectional movements, and sport-specific movements. Although many options for cardiopulmonary training exist, several common applications for post-ACLR will be discussed.

The primary focus of cardiopulmonary training during the first few months after ACLR is to maintain and (re)develop a baseline level of aerobic conditioning as the surgical graft heals and impairments in other physiologic systems (musculoskeletal, integumentary, nervous) are addressed. For example, interventions that target the musculoskeletal system typically aim to address deficits in range of motion and strength during the early postoperative timeframe, which impacts the mode and dosage options available for cardiopulmonary training. Many modes of exercise exist that address aerobic deconditioning while subjecting the healing ACL to minimal amounts of force. More traditional activities such as some aquatic exercise (considerations for
The graft strain with kicking motion are discussed below), upper extremity ergometry, cycling, or elliptical running may be viable options. Additional modalities such as battling ropes, kettlebell swings, and sled drags are less commonly discussed but allow for the same goal to be accomplished. Stationary biking can be used to address aerobic deconditioning during the early rehabilitation phase partly due to the minimal stresses placed on the healing graft. Fleming et al reported that stationary biking using toe clips placed a mean 1.7% peak strain on the ACL and did not differ between three power levels (75, 125, and 175 Watts), but peak ACL strain values were highly variable between subjects. This amount of strain during stationary biking is compared to 3.6% ACL strain observed during squatting and 4.4% during a 30 Newton-meter (NM) isometric quadriceps contraction at 15° knee flexion.

Various types of aquatic exercise (walking, deep water cycling, swimming) can be effective methods to improve aerobic conditioning early in the rehabilitation process as weight-bearing status can be more closely controlled in a buoyant aquatic environment. With swimming, careful attention needs to be given to the type of kick utilized. For example, the breaststroke kick, also known as the whip-kick, combines hip extension, knee extension, tibial external rotation, and ankle dorsiflexion, which places a relatively high load through the knee. For this reason, the breaststroke kick should be avoided in athletes until a complete recovery from ACLR has been achieved. Alternatively, the flutter kick, which is used in both the freestyle and backstroke, should be utilized as load is directed primarily to the quadriceps and patellofemoral interface. Underwater treadmill training is another option when clinically appropriate, as similar cardiorespiratory training effects for VO2, RPE, and respiratory exchange ratio were observed during underwater treadmill versus land-based running when performed at maximal exertion levels; however, HR was greater during land-based training comparatively. Further, a less rigorous training stimulus may occur (VO2) with underwater versus land-based training at submaximal workloads. Some types of underwater treadmills contain cameras to better visualize movement patterns, provide resistance jets, and allow for water depth adjustment via a movable deck. Exercising in water offers a unique environment with the added property of viscosity, where the amount of resistance experienced from viscosity is proportional to the velocity of a movement. From a multi-physiologic systems approach, one must consider the type of movements performed due to potential implications from water resistance on the musculoskeletal system.

Elliptical running can challenge the cardiopulmonary system to a similar extent to that of running on a treadmill and stair climbing while inducing a greater RPE of the lower extremities, despite similar overall RPEs. However, while elliptical training reduces reaction force during the early stance phase and loading rates during heel strike compared to walking, medial and posterior shear forces placed on the knee as well as peak hip flexor and knee extensor moment were greater; additionally, hip, knee, and ankle flexion angles were greater. Overground treadmill running is a commonly utilized cardiopulmonary training method post-ACLR, however, the vertical ground reaction forces applied to the lower extremity are typically much greater when compared to walking, but less than exercises such as unilateral or bilateral drop landing. However, recent technologies including the use of an unweighted treadmill, such as an AlterG® treadmill (AlterG, Inc., Fremont, CA), may provide a means to reduce loads to the lower extremities during running. A recent scoping review of 201 studies identified and examined 205 time-based criteria for return to running after ACLR, and found that the median time to allow return to running was 12 weeks, although it is unclear whether this timeframe is safe. Less than one in five studies reported clinical, strength, or performance-based criteria for decision making regarding return to running after ACLR, which is problematic. Rambaud et al recommended a combined goal- and time-based criteria to determine return to running after ACLR. Debate exists regarding whether an athlete’s kinematics and kinetics are altered when running on a treadmill versus flat ground, however, most research appears to suggest that any alterations are mild, including flight phase time, stride length, cadence, stride frequency, step length, support phase time, foot position, and lumbo-pelvic-hip kinematics. The mild gait alterations reported with treadmill running suggests that treadmill running is an appropriate step in returning to on-field/court running that may have a carryover effect; however, clinicians will need to determine whether their patient is appropriate for running based on several factors including surgical procedure, clinical status, and activity demands of the athlete. Progression to sport-specific or higher demand cardiopulmonary training is determined on an individual basis, but typically is begun once the athlete has demonstrated the ability to tolerate submaximal loads and built a foundation of cardiopulmonary fitness, not to mention the resolution of necessary impairments in other physiologic systems.

High-intensity interval training (HIIT) has become a popular aerobic conditioning method and involves short bouts (0.5 – 8 min) of moderate to high intensity activity, performed in the "severe" intensity domain near the anaerobic threshold, which are alternated with bouts of partial recovery performed at low-intensity or complete rest. This should not be confused with sprint interval training (SIT) which is performed at maximal effort for short bouts (<30s) followed by complete recovery. HIIT is often completed via running or biking, however, functional exercises utilizing one’s own body weight have also been explored. Previous research has found HIIT to be effective at improving lower extremity power, sprint speed, HR, VO2max, and muscular endurance as effectively or to a greater extent than traditional aerobic training and in a shorter amount of time. Research on HIIT training among healthy soccer and basketball athletes has produced similar findings. Wong et al found that vertical jump height, 10-m and 30-m sprint times, laps completed in the Yo-Yo intermittent recovery test, and maximal aerobic speed increased in professional soccer players after completing HIIT training compared to controls. In another study, VO2max, 1,000-m run time, and sprint performance improved after 5-weeks of HIIT training in adolescent soccer players. Aschendorf et al found that Yo-Yo intermittent recovery test as well as sprint and...
agility test performance without a basketball improved significantly in adolescent female athletes after undergoing a 5-week, basketball-specific HIIT program compared to controls. Specific application of HIIT training with patients post-ACLR has yet to be explored, so clinicians need to determine whether their patient is appropriate for the demands of HIIT training.

CONCLUSION

Cardiopulmonary system adaptations post-ACLR require careful assessment and intervention planning by the rehabilitation specialist. The integration of the cardiopulmonary system with other physiologic systems supports the aim of attaining efficient, goal-directed human movement after ACLR. Training the cardiopulmonary system after ACLR will in turn impact the health of the integumentary, musculoskeletal, and nervous systems. Selective cardiopulmonary testing and intervention should be integrated along the continuum of rehabilitation. By addressing cardiovascular deficits after ACLR within a multi-physiologic systems approach to resolve movement limitations, clinicians can help to optimize recovery and readiness for sport.

FUNDING

Dr. Severin receives funding support from the Foundation for Physical Therapy Promotion of Doctoral Studies (PODS) II Scholarship, The APTA Academy of Cardiovascular and Pulmonary Physical Therapy, and The Illinois Physical Therapy Foundation.

ACKNOWLEDGEMENTS

None.
